THE VALIDITY OF REAL-TIME DATA GENERATED BY A WEARABLE MICROTECHNOLOGY DEVICE.
ABSTRACT

The purpose of this study was to investigate the validity of global positioning system (GPS) and micro-electrical-mechanical-system (MEMS) data generated in real-time via a dedicated receiver. Post-session data acted as criterion as it is used to plan the volume and intensity of future training and is downloaded directly from the device. 25 professional rugby league players completed two training sessions wearing a MEMS device (Catapult S5, firmware version: 2.27). During sessions, real-time data was collected via the manufacturer receiver and dedicated software (Openfield v1.14) which was positioned outdoors at the same location for every session. GPS variables included total-, low- (0 to 3 m s⁻¹), moderate- (3.1 to 5 m s⁻¹), high- (5.1 to 7 m s⁻¹) and very-high-speed (> 7.1 m s⁻¹) distances. MEMS data included total session PlayerLoad™. When compared to post-session data, mean bias for total-, low-, moderate-, high- and very-high-speed distances were all trivial, with the typical error of the estimate (TEE) small, small, trivial, trivial and small respectively. Pearson correlation coefficients for total-, low-, moderate-, high- and very-high-speed distances were nearly perfect, nearly perfect, perfect, perfect and nearly perfect respectively. For PlayerLoad™, mean bias was trivial whilst TEE was moderate and correlation nearly perfect. Practitioners should be confident that when interpreting real-time speed-derived metrics, the data generated in real-time is comparable to that downloaded directly from the device post-session. However, practitioners should refrain from interpreting accelerometer derived data (i.e. PlayerLoad™) or acknowledge the moderate error associated with this real-time measure.

KEY WORDS: global positioning systems, accelerometers, PlayerLoad™, training load
INTRODUCTION

Quantifying the training and competition loads placed upon team sport players is an important process to promote adaptations and manage negative outcomes (e.g. injury).\textsuperscript{4,6} Global positioning systems (GPS) and micro-electrical-mechanical-systems (MEMS) are now commonly utilised to measure the external loads (e.g., walking, running, sprinting distances) accrued by athletes.\textsuperscript{10} Strength and conditioning coaches ‘download’ this data directly from the device (i.e. \textit{post-session} data) to calculate training loads over longitudinal periods (e.g. 28- and 7-day averages of training load [i.e. acute:chronic workload ratio]) to inform the planning of both the volume and intensity of future field-based training sessions.\textsuperscript{4} Since the initiation of GPS and MEMS data within team-sports, microtechnology companies have provided the capability to monitor these loads in \textit{real-time} via a dedicated receiver (Figure 1) to increase the control of training prescription.\textsuperscript{2} For example, if a strength and conditioning coach identified a need to limit the amount of high-speed-running during the session on that day, it is perceived that this can then be accurately controlled in \textit{real-time} as players complete the session.

Although both derived from GPS and MEMS, \textit{real-time} data arrives at the end-user differently, via a specific receiver, whereas \textit{post-session} data is downloaded directly from the device. Therefore, at present, practitioners should not assume that the data they receive in \textit{real-time} during the session is comparable to that which they use to inform the planning of training (e.g. \textit{post-session} data). As the volume and intensity targets for each player are underpinned by longitudinal analyses conducted using \textit{post-session} data and subsequently controlled in \textit{real-time}\textsuperscript{7}, understanding the agreement between \textit{real-time} and \textit{post-training} data is an important consideration. However, despite the exponential increase in research relating to the validity and reliability of GPS and MEMS devices to quantify distance and speed variables specifically\textsuperscript{9}, only a single study (conducted in 2010), has investigated this
aspect of training load monitoring. By comparing the signal (smallest meaningful difference [SMD]) to the noise (typical error [TE]) of real-time to post-session data, Aughey and Falloon (2010) found that whilst the signal exceeded the noise (SMD = 134.6 m; TE = 55.8 m) for total distance, this was reduced considerably during jogging (4.2 to 5.0 m·s⁻¹; SMD = 33.5 m; TE = 30.1 m) and running (5.0 to 6.9 m·s⁻¹; SMD = 31.9 m; TE = 31.3 m). In particular, the noise exceeded the signal during real-time collection for sprinting (SMD = 17.3 m; TE = 23.7 m). The above findings showed that only total distance demonstrated an acceptable signal:noise ratio, suggesting that real-time data possesses limited validity and applicability to practice. However, despite the previous findings, developments in MEMS, its associated software and the increased number of variables available during real-time analysis, mean a reinvestigation is warranted. Strength and conditioning coaches who use microtechnology devices in real-time require confidence that this data is comparable to that which is used to conduct detailed analyses of the accumulation and distribution of training load. Therefore, the aim of the current study was to re-establish the validity of real-time MEMS data compared to post-session data derived from a commonly used software platform (Catapult Openfield).

METHODS

Experimental Approach to the Problem

An observational research design was conducted in which the participants completed 2 training sessions whilst wearing a GPS and MEMS device on the same artificial pitch and at the same time of day with environmental conditions clear for both testing sessions (mean temperature: 6 ± 1°C; relative humidity: 88 ± 2%). The training sessions were focused on enhancing the squads technical and tactical capabilities (i.e. skills based training) during the initial stages of the 2017 competitive season. The lead researcher was not involved in the
prescription of training content relating to the sessions. Real-time GPS and MEMs data was generated during each session and compared to that downloaded directly from the device post-session. Therefore, players provided 40 session observations in total comprising of both real-time and post-session data per observation. The lead researcher was experienced (> 5 years) in operating the microtechnology system and players possessed full familiarisation with the devices as part of their regular monitoring practices (i.e. > 3 seasons).

Subjects

Twenty male professional rugby league players (age: 27.0 ± 5.0; height: 184.3 ± 6.9 cm; weight: 94.4 ± 11.7 kg) from one European Super League club participated in the current study. Ethics approval was gained by the universities Institutional Review Board conforming to the spirit of the Helsinki declaration and written informed consent was gained from all participants following information of the benefits and risks of the investigation.

Procedures

During all sessions, players wore a GPS and MEMS device (Optimeye S5, Catapult Innovations, Scoresby, Victoria) which included 10 Hz GPS, 100-Hz tri-axial accelerometer, gyroscope and magnetometer (firmware version 2.27; Figure 1). This positioned between the scapulae within a manufacturer designed vest and operated by the lead researcher according to typical procedures.\(^7\) 10 Hz GPS has been reported to be valid and reliable for quantifying post-session distance and speed measurements.\(^7\) The mean number of satellites and horizontal dilution of precision (HDOP) during data collection was 14 ± 1 and 0.6 ± 0.2 respectively.

During each training session, the real-time receiver (2.4 GHz radio frequency; firmware version 2.27; Figure 1) was connected to a laptop (Dell XPS; Windows 10 Pro (x64); Intel Core i7; 2.6 GHz; 16 GB random access memory) via universal serial bus (USB) which collected the real-time variables through Catapult Openfield software (v1.14, Catapult...
Innovatons, Scoresby, Victoria). This was positioned outdoors on a grass pitch at the same location for every training session, positioned 5 metres away from the ‘in-goal’ line so that at any time during the session, players were within 5 to 105 metres of the receiver. This distance falls within manufacturer recommended radius of 150 metres (personal communication with manufacturers). During each session, periods of training were ‘clipped’ in real-time so that no data recorded for analysis included scheduled periods of no activity (i.e. drinks breaks). These periods were automatically synchronised between real-time and post-training conditions within the software.

***** INSERT FIGURE 1 HERE*****

The total distance (m) covered during a training session was compared for real-time and post-training within arbitrarily demarcated speed zones. This included low- (0 to 3 m·s⁻¹), moderate- (3.1 to 5 m·s⁻¹), high- (5.1 to 7 m·s⁻¹) and very-high-speed-distances (> 7.1 m·s⁻¹). Derived from the tri-axial accelerometer, the total PlayerLoad™ accumulated in each training session was compared between real-time and post-training conditions. PlayerLoad™ is a modified vector magnitude which aims to encapsulate all velocity, acceleration, change of direction and collision demands experienced by players.² It is expressed as the square root of the sum of the squared instantaneous rate of change in acceleration in each of the three vectors (X: mediolateral, Y: anterio-posterior, and Z: vertical) divided by 100 and expressed in arbitrary units (AU).²³

**STATISTICAL ANALYSES**

Based on 90% confidence limits (90% CL), the agreement between the criterion measure (post-session data for each variable) and the practical measures (real-time data for each variable) were assessed using an excel spreadsheet⁵ to calculate the mean bias, typical error of the estimate (TEE) and Pearson correlation coefficient. The standardised mean bias was
rated as *trivial* (< 0.19), *small* (0.2 to 0.59), *medium* (0.6 to 1.19) or *large* (1.2 to 1.99).\(^5\) The standardised TEE was rated as *trivial* (< 0.1), *small* (0.1 to 0.29), *moderate* (0.3 to 0.59) or *large* (> 0.59).\(^5\) Correlation coefficient magnitudes were rated as *trivial* (0 to 0.09), *small* (0.1 to 0.29), *moderate* (0.3 to 0.49), *large* (0.5 to 0.69), *very large* (0.7 to 0.89), *nearly perfect* (0.9 to 0.99) and *perfect* (> 0.99).\(^5\)

**RESULTS**

The mean duration of the sessions were 50.3 ± 2.6 mins. Table 1 highlights the mean ± standard deviation of the external loads (PlayerLoad™ [AU], total-, low-, moderate-, high- and very-high-speed distances [m]) plus the standardised mean bias, TEE and Pearson correlation coefficients all with 90% CL for *real-time* and *post-session* conditions.

**** INSERT TABLE 1 HERE ****

The regression equation to estimate *post-session* data from *real-time* data for each variable is:

\[ Y = \text{intercept} + (\text{slope} \times X) \]

Where \(Y\) is the estimated *post-session* data for a given variable and \(X\) is the *real-time* data for a given variable.

The regression equations for each variable are:

*Total-Distance:*

\[ Y = -467.601 + (1.152 \times X) \]

*Low-Speed Distance (0 to 3 m·s\(^{-1}\)):*

\[ Y = -545.544 + (1.246 \times X) \]
Moderate-Speed Distance (3 to 5 m\(\cdot\)s\(^{-1}\)):

\[ Y = -5.814 + (0.998 \times X) \]

High-Speed Distance (5 to 7 m\(\cdot\)s\(^{-1}\)):

\[ Y = -1.959 + (0.948 \times X) \]

Very-High-Speed Distance (> 7 m\(\cdot\)s\(^{-1}\)):

\[ Y = 0.528 + (0.804 \times X) \]

PlayerLoad\(^{TM}\):

\[ Y = 27.899 + (0.922 \times X) \]

**DISCUSSION**

This study assessed the agreement between GPS and MEMS data derived by either real-time or post-session (criterion) methods in professional rugby league players. The findings suggest that real-time speed-derived variables determined from 10Hz GPS (Optimeye S5, Catapult Innovations, Scoresby, Victoria) can provide valid quantification of the external loads.
accrued by players when compared to data downloaded directly from the device. However, practitioners should be cautious of interpreting real-time accelerometer derived data.

For strength and conditioning coaches working with team-sport players, controlling and developing their high-speed running exposure has been suggested to be an important process to reduce negative training outcomes such as injury. Given the trivial error between real-time and post-session data, the findings of the current study suggest that practitioners should be confident of making decisions in real-time regarding the accumulation of a players high-speed (5 to 7 m∙s⁻¹) distance. However, they should acknowledge the small error between post-session and real-time when quantifying very-high-speed (> 7.1 m∙s⁻¹) running exposure. The current findings somewhat support earlier research using previous models of the microtechnology device (MinimaxXX, Team Sport 2.0, Catapult Innovations) which report poorer agreement for very-high-speed running (i.e. > 7 m∙s⁻¹) compared to lower speeds, although in the current study very-high-speed running was still found to possess acceptable error.

For collision-based team-sports (e.g. rugby league, American football), quantifying collision- and accelerative-based activity during training and competition is an important aspect and therefore, monitoring accelerometer derived measures in real-time is an attractive capability for practitioners. However, whilst post-session PlayerLoad™ data has been found to be both reliable and valid, in real-time, moderate errors were found when compared to the data downloaded directly from the device. It is unknown why real-time PlayerLoad™ data demonstrated greater errors compared to speed-derived methods. It is possible that differences in how the real-time receiver receives data from the 100Hz tri-axial accelerometer compared to 10Hz GPS can explain the greater errors associated with real-time PlayerLoad™. Therefore, practitioners should ideally refrain from interpreting real-time PlayerLoad™ during training and competition but should they wish to estimate post-session
from *real-time* data, the regression equations provided in the current study can be used whilst acknowledging the error associated with this.

**PRACTICAL APPLICATIONS**

Practitioners can be confident in making decisions of the training load imposed using data that calculates the *real-time* distance covered in low- (0 to 3 m·s⁻¹) to high-speed (5.1 to 7 m·s⁻¹) thresholds derived from the Catapult S5 microtechnology device. However, practitioners should focus on speed-derived methods given the errors associated with *real-time* tri-axial accelerometer data.
