Article (Accepted Version)

The aim of the Leeds Beckett Repository is to provide open access to our research, as required by funder policies and permitted by publishers and copyright law.

The Leeds Beckett repository holds a wide range of publications, each of which has been checked for copyright and the relevant embargo period has been applied by the Research Services team.

We operate on a standard take-down policy. If you are the author or publisher of an output and you would like it removed from the repository, please [contact us](#) and we will investigate on a case-by-case basis.

Each thesis in the repository has been cleared where necessary by the author for third party copyright. If you would like a thesis to be removed from the repository or believe there is an issue with copyright, please contact us on openaccess@leedsbeckett.ac.uk and we will investigate on a case-by-case basis.

Title: The Effect of Hypermobility on the Incidence of Injury in Professional Football: a multi-site cohort study

<H1> ABSTRACT

Background: A recent study demonstrated joint hypermobility increased the incidence of injury in an elite football team utilising a univariate statistical model.

Objectives: To compare injury incidence between hypermobile and non-hypermobile elite football players incorporating a multi-site design and multivariate inferential statistics.

Methods: 80 players comprising 3 English Championship football teams were followed prospectively during the 2012-2013 season. Joint hypermobility was assessed according to the 9-point Beighton Criteria at the start of the study period. A cut-off score of ≥ 4 categorised a participant as hypermobile. Player exposure and time-loss injuries were recorded throughout.

Results: Mean \pm standard deviation incidence of injuries was 9.2 ± 10.8 injuries/1000h. The prevalence of hypermobility was 8.8%. Hypermobiles had a tendency for higher injury incidence (mean [95% confidence interval] difference, 5.2 [0.9-2.7] injuries/1000 h; $p = 0.06$). Cox regression analyses found training exposure to be highly significant in terms of injury risk ($p < 0.001$) for all participants. Non-hypermobiles had a lower injury risk ($p = 0.11$), according to the Cox model, which is suggestive but not conclusive that hypermobility predisposes injury risk.

Conclusions: Hypermobility showed a trend towards increased risk of injury. Training exposure is a significant injury risk factor in elite football.

<H1> INTRODUCTION

Hypermobility refers to range of motion that exceeds normal limits at some or all joints in the body (Russek, 1999). Generalised joint hypermobility is a term used to describe hypermobility that exists in the absence of musculoskeletal pain and rheumatologic disease and takes into account an individual's age, sex and ethnicity (Simpson, 2006). Generalised joint hypermobility is classified as a heritable connective tissue disorder and represents a qualitative variation in the structural protein collagen (Simmonds and Keer, 2007). The Beighton scale is a validated tool used to assess the presence of generalised joint hypermobility (Remvig et al, 2007). Individuals are assessed on a 9-point system for excessive joint range of motion at the following anatomic sites: fifth finger, thumb, elbow, knee, and trunk. The British Society of Rheumatology recommends a Beighton score ≥ 4 to categorise an individual as hypermobile (Remvig et al, 2007).

Professional football is a contact sport with an estimated incidence of injury between 24 and 30 injuries per 1000 hours of match play and between 3 and 5 injuries per 1000 hours of training with a high prevalence of lower limb injuries in which hamstring strains predominate (Walden et al, 2001; Ekstrand, 2008; Ekstrand et al, 2011). The findings of a systematic review with meta-analysis suggests that hypermobility increased the risk of knee joint injury during contact sports, although there was no evidence that hypermobility affected the risk of ankle joint injury (Pacey et al, 2010). Two longitudinal studies included in the review investigated female football players - cohort comprised professional and semi-professional athletes - over a ten year period and found that hypermobility was a risk factor for injury (Östberg and Roos, 2000; Soderman et al, 2001). Collinge and Simmonds (2009) were the first to investigate hypermobility as a risk factor for injury in English male professional football. The authors reported the prevalence of joint hypermobility to be between 21 and 42% depending on the threshold cut-off score used to categorise hypermobility. Similar injury rates for those players categorised as hypermobile and non-hypermobile were found

but a tendency for hypermobile participants to miss more competitive matches and training sessions was reported.

Konopinski et al (2012) conducted a cohort study at a first tier English Premier League male football club and found the incidence of injury was greater for players categorised as hypermobile than those categorised as non-hypermobile. This resulted in more missed days of match-play and training, recommending that pre-signing medical screening should include the assessment of generalised joint hypermobility.

To date, studies in professional male football have only been conducted at a single-site (i.e. one football club) reducing external validity of the findings. In addition, data has been analysed using univariate statistics that do not control for interactions or confounding risk factors for injury. Differences in definitions of injury, monitoring of exposure, measures and threshold scores for categorising hypermobility make comparison between studies difficult. The aim of this study was to investigate hypermobility as a risk factor for injury occurrence and to compare the incidence of injury per thousand hours of exposure between hypermobile and non-hypermobile elite football players utilising a multi-site design and multivariate inferential statistics.

<H1> METHODS

<H2> Participants, Recruitment and Selection

A prospective cohort study was conducted during the 2012-2013 season. All clubs in the English Championship were invited to participate by providing the Head Physiotherapist at each club with a Study Pack that included a description of the study plan including operational procedures and a letter of invitation. Clubs that expressed interest were sent a more detailed Study Manual before being formally enrolled as a study site. All players with a professional contract at each enrolled club provided written consent to allow their data be used in the study including pre-season clinical assessment, match and training exposure and reported injury and illness throughout the season. Ethical approval was obtained from the Faculty of Health and Social Sciences Ethics Committee at Leeds Beckett University and study data was coded for anonymity.

<H3> Procedure

Each club selected a designated member of the medical team to be responsible for collecting data and forwarding it to the data custodian from the investigating team (<initials here>). On day 1 of pre-season, hypermobility status was measured using the 9-point Beighton scale (Table 1) using a cut-off point of ≥ 4 to categorise a participant as hypermobile, consistent with previous investigations (Östenberg and Roos, 2000; Collinge and Simmonds, 2009; Konopinski et al, 2012). Bilateral elbow and knee extension values were measured using a goniometer to dichotomise joints as hypermobile or non-hypermobile (Norkin and White, 1995). Knee and elbow goniometric measurement have been shown to have good intra-rater reliability and moderate inter-rater reliability (Watkins et al, 1991; Chunang et al, 2007). Anthropometric measurements and playing position were also recorded. Data relating to pre-existing injuries at enrolment were not included in the study.

Table 1 The Brighton Scale

Test	Criteria	Right	Left
Fifth finger extension	Passive extension > 90°	1	1
Wrist flexion thumb abduction	Passively abduct the thumb to oppose the flexor aspect of the forearm	1	1
Elbow extension	Hyperextension > 10°	1	1
Trunk and hip flexion	Knees fully extended, forward trunk flexion, able to place palms flat on the floor	1	
Knee extension	Hyperextension > 10°	1	1

Data collection procedures followed the guidelines set out in the Union of European Football Associations (UEFA) consensus document for studies investigating football injury (Fuller et al, 2006). A time loss definition of injury was used where an injury was defined as that sustained during training or match play causing the player to interrupt the session or miss the subsequent session. A reinjury was defined as an injury that was the same type and at the same anatomic site irrespective of when it occurred over the season. Injury severity was categorised according to length of absence from football as: slight (0 days), minimal (1-3 days), mild (4-7 days), moderate (8-28 days), severe (>28 days), or career ending.

Each injury was recorded on a standardised injury card for each player. Absence due to illness or otherwise was not included in the injury audit analysis. Injuries were classified according to type, location, side and whether the injury was a recurrence (i.e. re-injury). A free-text section allowed the recording of diagnosis specifics. Re-injury was defined as an injury of the same type and anatomic site, occurring after return to full participation from the original injury. A non-applicable injury was defined as absence not due to trauma or overuse, for example elective surgery.

Exposure was recorded on monthly attendance record forms, which included all training and match exposure to the nearest minute. Absence from football participation due to injury, international duty or otherwise were recorded on the attendance form. Injuries incurred whilst on international duty were not considered inclusive. Participants were deemed injured until able to participate fully in team training or match-play. Incidence of injury was derived from the exposure form and calculated as the number of injuries per 1000 hours of exposure.

Monthly exposure sheets, and injury and illness information was coded for anonymity and returned to the investigating team via email on a monthly basis. Information was checked for ambiguous or missing data and medical teams contacted for clarification.

<H4> Data Analysis

Comparisons between hypermobile and non-hypermobile participants were made using t-tests, Poisson tests, and a Cox Regression model. Unpaired t-tests were used to compare demographic, anthropometric, and exposure data between groups. Within-participant comparisons of the number of injuries in training and match play were made using Wilcoxon signed-rank tests on pairwise differences. The incidence of injuries per 1000 hours of exposure was calculated for hypermobile and non-hypermobile participants, and compared using Poisson tests. The influence of hypermobility as a potential predictor variable for risk of injury was analysed by means of Cox regression analyses. Analyses were performed using R version 3.0.2 (R Core Team, Vienna, Austria), with statistical significance set at $P \leq .05$.

<H1> RESULTS

<H2> Characteristics of the Study Group

Twenty-four football clubs from the English Championship were invited to participate in the study, of which three enrolled. There were 80 male participants that provided pre-season assessment data (mean \pm standard deviation [SD] age, 24.5 ± 4.6 years) including 10 goalkeepers, 30 defenders, 24 midfielders, and 16 attackers. Mean \pm SD Beighton score was 1.30 ± 1.47 of a possible score of 9. Seventeen participants went out on loan to different teams during the course of the study period. The Poisson tests and Cox model accounted for this data censoring i.e. it was conducted on 80 participants and designed to control for drop-outs. In order to avoid data distortion, all other data are reported for the 63 players who were present for the entire study period.

The prevalence of hypermobility was 8.8% with 7 participants scoring 4 or more on the Beighton scale. There were no statistically significant differences between hypermobile and non-hypermobile participants in age, height, weight or training and/or match exposure (Table 2). However, analysis of age between the three participating teams demonstrated that one team had a significantly older squad (mean \pm SD age 27.12 ± 4.01 years) compared with the other two teams (23.49 ± 4.74 and 23.34 ± 4.72 years, $p < 0.05$, unpaired t-test).

^cUnpaired t test.

<H2> Univariate Analysis of Injuries

A total of 117 injuries, including 15 multiple injuries and 17 re-injuries, were recorded for the 63 participants who were monitored for the full duration of the study. The mean incidence of injuries for all 80 participants was 8.4 injuries/1000 h ([95% CI = 0.72-2.48], p = 0.16, Poisson test) (Table 3). There was no statistically significant difference in mean incidence of injuries between hypermobile and non-hypermobile participants when non-applicable injuries were included (hypermobile = 14.0 injuries/1000 h, non-hypermobile = 8.8 injuries/1000 h, [95% CI = 0.88-2.68], p = 0.06, Poisson test), or excluded (hypermobile = 11.4 injuries/1000 h, non-hypermobile = 8.1 injuries/1000 h, [95% CI = 0.72-2.48], p = 0.16, Poisson test) (Table 3).

Table 3 Analysis of Injuries^a

	All Participants	Hypermobile	Non-hypermobile	P
Number of injuries during training + match play per player (tally)	2.05 ± 1.63 (117)	3.00 ± 1.73 (12)	1.97 ± 1.61 (105)	0.57 ^b
Number of training injuries per player (tally)	0.73 ± 0.90 (46)	0.40 ± 0.55 (2)	0.76 ± 0.92 (44)	0.22 ^b
Number of match injuries per player (tally)	1.13 ± 1.28 (71)	2.00 ± 1.58 (10)	1.05 ± 1.23 (61)	0.26 ^b
Total incidence of injury (training + match), per 1000 h	8.40	11.40	8.1	0.16 ^c (95% CI, 0.72-2.48)
Total incidence of injury (training + match), per 1000 h (including non-applicable injuries)	9.20	14.00	8.80	0.06 ^c (95% CI, 0.88-2.68)
Incidence of training injuries, per 1000 h	4.10	2.20	4.20	0.9 ^c (95% CI, 0.06-1.94)
Incidence of match injuries, per 1000 h	29.90	51.50	28.10	0.053 ^c (95% CI, 0.88-3.49)
Total days missed due to injury (training + match)	42.87 ± 46.42	64.00 ± 49.92	41.05 ± 46.11	0.3 ^d (95% CI, -38.1-84.0)
Training days missed due to injury	20.70 ± 24.28	29.80 ± 24.57	19.91 ± 24.31	0.3 ^d (95% CI, -20.0-39.9)
Match days missed due to injury	10.02 ± 11.75	15.20 ± 14.32	9.57 ± 11.54	0.3 ^d (95% CI, -11.9-23.2)

^aMean ± standard deviation summary data (unless otherwise stated). P represents comparisons between hypermobile and non-hypermobile participants.

^bWilcoxon signed ranks test.

^cPoisson test.

^dUnpaired t test.

Of the sixty-three participants followed for the duration of the study, fifty-one sustained at least 1 injury (5 hypermobile, 46 non-hypermobile). Twelve non-hypermobile participants did not incur injury, however all 7 hypermobile players were injured. Fourteen participants (22.2%) sustained at least one re-injury during the season, three of these 14 players were hypermobile. Although not

statistically significant, hypermobile participants demonstrated a greater tendency to experience a re-injury (hypermobile, n=3/7; non-hypermobile, n= 11/56; Fisher exact test, p = 0.11), with a relative risk of 2.51 (95% CI, 0.85-7.43).

Participants sustained a higher mean [95% CI] injury rate during match play (29.9 [0.88-3.49] injuries/1000 h) than during training (4.1 [0.06-1.94] injuries/1000 h), with a mean (95% CI) difference of 25.8 (5.17-10.57) injuries/1000 h ($p < 0.000$). There was no statistically significant difference in mean incidence of training injuries between hypermobile (2.2 injuries/1000 h) and non-hypermobile participants (4.2 injuries/1000 h; mean difference [95% CI] = 2.0 [0.06-1.94] injuries/1000 h, $p = 0.9$, Poisson test) (Table 3). Mean incidence of injuries during match play was greater for hypermobile participants (51.5 injuries/1000 h) compared with non-hypermobile participants (28.1 injuries/1000 h; mean difference [95% CI] = 23.4 [0.88-3.49] injuries/1000 h, $p = 0.053$, Poisson test) (Table 3), although this just failed to reach statistically significance.

Of the 63 players that remained at their parent club for the duration of the season, there was no statistically significant difference in the mean \pm SD number of training days missed due to injury (hypermobile = 29.8 ± 24.57 days, non-hypermobile = 19.91 ± 24.31 days, mean [95% CI] difference = 9.9 [-20.0-39.9], $p=0.3$, unpaired t test), or match days missed due to injury (hypermobile = 15.2 ± 14.32 days, non-hypermobile = 9.57 ± 11.54 mean [95% CI] difference = 5.6 [-11.9-23.2], $p=0.3$, unpaired t test) (Table 3).

There were 117 unique injury mechanisms (Table 4). Hypermobile participants suffered a higher percentage of contact and jumping/landing injuries relative to non-hypermobiles. Of the 117 unique injuries, comprising 128 different injury locations (one unique injury mechanism may result in more than one site of injury) (Table 5) and 122 injury types (e.g. fracture dislocation of the ankle would represent two injury types - 'fracture' and 'sprain/ligament injury') (Table 6). Twelve unique injuries

were attributed to the hypermobile participants. Half of injuries for all participants were classified as moderate severity; however there were no statistically significant differences between hypermobile and non-hypermobile groups according to injury severity. Lower limb injuries were most common, with the most frequent location of injury being the thigh (47/128, 37%) and ankle (19/128, 15%) (Table 5). In terms of injury type, muscle rupture/tear/strain was most common (48/122, 39%) (Table 6). Three of the 12 unique injuries (25%) suffered by hypermobile participants were located at the knee (2 ligament sprains, 1 cartilage injury). Non-hypermobile participants suffered 17 knee injuries (16%), 8 of which were ligament sprains. This data failed to reach statistical significance (Fisher exact test, p=0.59). Average days lost for knee injury in the hypermobile group was 48.8 versus 22.5 in the non-hypermobile group.

Table 4 Injury Mechanism

Mechanism	Hyper Injuries	Non-hyper Injuries	Total	Hyper Injuries	Non-hyper Injuries	Total
Running/sprinting	5	37	42	42%	35%	36%

<H3> Multivariate Analysis of Injuries

The Cox model included the following as independent prognostic factors for injury risk; training exposure per week, game exposure per week, age, and hypermobility status. Data was clustered on player and stratified on position and club. Akaike Information Criterion (AIC) testing confirmed stratification improved validity of the Cox model. Training exposure was highly significant in terms of

increasing injury risk ($p = 0.000$, Table 7). An extra hour per week of training increases the daily hazard by a factor of 1.4 – an increase of 40% (Table 7; Figure 1). Game exposure per week did not increase injury risk ($p = 0.48$, Table 7). Non-hypermobile participants had a lower injury risk ($p = 0.11$), which was suggestive but not conclusive that hypermobility is a risk factor for injury (Table 7). Non-hypermobility increased the daily hazard by a factor of 0.67 – a decrease of 33% (Table 7; Figure 2). There was no tendency towards a heightened injury risk with increasing age ($p = 0.2$).

<H1> DISCUSSION

The prevalence of hypermobility in a multi-site sample of 80 English Championship football players during the 2012-2013 was 8.8%, with a mean ± SD incidence of 9.2 ± 10.8 injuries/1000 h. The results show a tendency for participants with hypermobility to experience more injuries in match-play and overall (training plus match-play), just failing to reach statistical significance. There was no difference in days missed from training and match play between hypermobile and non-hypermobile participants. The low number of participants diagnosed with hypermobility is likely to have contributed to low statistical power and the lack of significance found with inferential statistical testing resulting in a type 2 error. With the observed injury rates and total exposures, the power was 0.2, R version 3.0.2 (R Core Team, Vienna, Austria). Had the injury rates been consistent with a previous study for hypermobile participants (Konopinski et al, 2012), the predicted power is 0.98, R version 3.0.2 (R Core Team, Vienna, Austria). We suggest that injury rate may differ between the English Championship and English Premier League.

Hypomobility prevalence in an English Premier League football team was found to be 33.3% using a Beighton cut-off score of 4 or above (Konopinski et al, 2012). Collinge and Simmonds (2009) reported the prevalence of joint hypomobility in a second tier professional football team to be 21% using Beighton when a cut-off score of 4 or above was applied and 42% when a score of 5 or greater was used. The prevalence of hypomobility per se varies from 5% to 43% (Simmonds and Keer, 2007), suggesting that a prevalence of 8.8% is not atypical. The variability in reported prevalence may be due to operational differences in assessing hypomobility – case identification – or inherent

within the study population demographic i.e. age, gender and ethnicity. One of the teams in the present study had a significantly older squad compared with the other two teams involved. Collinge and Simmonds (2009) and Konopinski et al (2012) studied younger squads – mean \pm SD 24.48 \pm 4.8 and 22.5 \pm 4.17 respectively. The older squad within the cohort for the present study may in part account for the lower hypermobility prevalence. In a systematic review of 18 studies, 7 different objective measures of hypermobility were used, involving 10 differing measurement methods (Pacey et al, 2010). The Beighton scale is a popular diagnostic tool as it is easy to administer, however upper limb measures predominate and it gives no indication of the degree of hypermobility. The Brighton Criteria incorporates the Beighton score but also recognises symptoms and other characteristics associated with connective tissue laxity (Grahame et al, 2000) (Table 8). It is possible that unique use of the Brighton criteria under-represented the number of elite football players participating in this study with hypermobility. For example, the Brighton Criteria allow for the scenario whereby an individual may have a Beighton Score of 1 (minor criterion met) plus 3 other minor criteria associated with chronic and acute injury – dislocations, spondylosis, hernia (Table 8). Anecdotal evidence in elite football suggests that it is not uncommon for such pathologies to coexist.

Table 8 Brighton Criteria

Major Criteria
Beighton score of 4/9 or greater.
Arthralgia for longer than 3 months in 4 or more joints.
Minor Criteria
Beighton score of 1, 2, 3/9.
Arthralgia (> 3 months) in one to three joints or back pain (> 3 months); spondylosis, spndylosis, spondylolisthesis.
Dislocation/subluxation in more than one joint or in one joint on more than one occasion.
Soft tissue rheumatism > 3 lesions (e.g. epicondylitis, tenosynovitis, bursitis).
Marfanoid habitus (tall, slim, span/height ratio > 1.03, upper:lower segment ratio < 0.89, arachnodactyl [positive Steinberg/wrist signs]).
Abnormal skin: striae, hyperextensibility, thin skin, papyraceous scarring.
Eye signs: drooping eyelids or myopia or antimongoloid slant.
Varicose veins or hernia or uterine/rectal prolapse.

JH diagnosed in the presence of two major criteria or, one major and two minor criteria, or four minor criteria.

Mean incidence of injury during training and match play (4.1 injuries/1000 h, 29.9 injuries/1000 h respectively) were similar to previous reports (3 to 5 training injuries/1000 h, 24 to 30 match

injuries/1000 h) (Walden et al, 2001; Ekstrand, 2008; Ekstrand et al, 2011; Ekstrand et al, 2013) . Our findings are suggestive that hypermobility increases injury risk in football, consistent with previous studies (Pacey et al, 2010; Konopinski et al, 2012). Thigh muscle ruptures/tears/strains were most common for all participants, in keeping with current epidemiological injury studies on professional football players (Walden et al, 2001; Ekstrand, 2008; Ekstrand et al, 2011; Ekstrand et al, 2013).

A major secondary finding from the study was that one extra hour per week of training significantly increased injury risk within the population as whole. The majority of published research investigating injury risk in elite football has focused on intrinsic risk factors such as age (Hawkins and Fuller, 1999; Ekstrand, 2008), previous injury (Arnason et al, 2004; Häggglund et al, 2006; Walden et al, 2006), muscle flexibility (Witvrouw et al, 2003; Arnason et al, 2004) , and muscle strength (Russek, 1999) rather than training load. Previous studies in rugby league and Australian Rules football have shown an increase in training load significantly increases incidence of injury (Gabbett, 2004; Rogalski et al, 2013). Gabbett (2004) followed 79 semi-professional rugby league players throughout the course of one season. Training intensity was measured using a rating of perceived exertion (RPE). Training load was calculated by multiplying RPE by training duration. Training intensity ($r = 0.83$), duration ($r = 0.79$) and load ($r = 0.8$) significantly increased incidence of injury ($p < 0.05$) (Gabbett, 2004). Rogalski et al (2013) used a similar methodological approach in a sample of 46 elite Australian Rules football players. Increases in load relative to the previous week ($OR = 2.58$) significantly increased injury risk ($p < 0.05$) (Rogalski et al, 2013). The present study is the first to report the relationship between training duration and injury risk in professional football.

<H2> Study shortcomings

A larger sample size is required to improve the study power. Small to moderate associations between risk factor and injury have been estimated to require over 200 unique injury cases (Bahr and Holme, 2003). The present study had 117 unique injury cases within the entire sample. In

addition, a single season prospective design was used in this study and a consecutive season approach would have been beneficial to enhance external validity. The study suffered from recruitment difficulties as only 3 from a possible 24 clubs enrolled.

The Beighton scale was employed in the current study as it is quick and easy to administer and despite its use in previous studies we are increasingly concerned that it may not have been sensitive enough to confirm a diagnosis of hypermobility in athletic populations. The moderate inter-rater reliability of the Beighton scale may be a limitation in our study given that participants were measured by different clinicians. This may account for the low prevalence of generalised joint hypermobility found in the study. Within the Beighton Scale upper limb measures predominate and the scale provides limited information as to the degree of hypermobility. Future studies may wish to consider better methods of identifying those athletes for which hypermobility may be clinically significant.

Injury was defined in terms of time lost from football participation. This definition has been criticised due to the strong subjective component associated with time-loss due to injury (Konopinski et al, 2012). In addition to actual tissue damage, psychological issues i.e. anxiety and depression, may also influence return-to-play time scales. Anxiety causes heightened physiological arousal and physical sensations (Mallorqui-Bague et al, 2014). Clearly the time-loss definition is not free from error. However, the definition is relevant considering the increasing body of evidence that anxiety and depression are associated with hypermobility and the propensity for slower soft tissue healing rates in this population (Bulbena et al, 2011; Garcia-Campayo et al, 2011; Mallorqui-Bague et al, 2014). Training exposure was significantly associated with injury risk in the current study, however intrinsic training and match load were not observed. The likelihood is that the unique interaction between training load and duration is what affects injury rate. Future studies should incorporate global positioning sense (GPS) and heart rate (HR) data in order to calculate intrinsic load. Moreover, future

studies should record previous injury for participants at baseline to include in the Cox model, as previous research has consistently found it to be a predictor of injury risk.

<H3> Implications of Findings

Our findings suggest that hypermobility contributes to injury risk in professional football and we recommend that players should be routinely screened for hypermobility. Identification of hypermobility provides clinically relevant information in terms of injury prognosis, specific rehabilitative strategies and return to play time-scales. Sports Science and Medicine Departments should consider the effect of increasing training exposure on injury risk in professional football players. Future cohort studies investigating joint hypermobility in elite football should utilise a larger sample size and may wish to categorise players according to both the Beighton and Brighton Criteria.

<H4> Conclusion

There was a tendency towards increased incidence of injury in hypermobile elite-level football players in the English Championship. Increased training exposure represented an injury risk for all participants in the study.
